Summary

Live video streaming has long been projected as the killer application for Internet. In recent years with the deployment of increased bandwidth in the last mile, this promise finally turned into reality. There are competing technologies to deliver live video streaming: CDN (content delivery network) and P2P (peer-to-peer). CDNs provides end-users with the appearance of traditional client server approaches but enable content providers to handle much larger request volumes. At the same time, ISPs can also benefit from deploying CDN servers in their networks as it reduces the total amount of upstream and transit traffic. CDN provide excellent quality to end-users when the workload is within provisioning limits. P2P systems solve the scalability issue by leveraging the resources of the participating peers, while keeping the server requirement low. However, decentralized uncoordinated of P2P operation comes with undesirable side effects: unfairness in the face of heterogeneous peer resources, network unfriendliness, etc. On the other hand, the growth of video traffic is also contribute to increases of power consumption and it's need to be considered.

In this research, Bittorrent as one of the most popular and successful P2P applications in the current Internet is taken as example the study of uncoordinated P2P operation. First problem to be addressed in this research is how to reveal the topology of real Bittorrent swarms, how dynamic the topology is, and how it affects overall behavior. We study of Bittorrent networks, where real-world Bittorrent swarms were measured using a rigorous and simple method in order to understand the Bittorrent network topology. We propose the Bittorrent Peer Exchange (PEX) messages to infer the topology of Bittorrent swarms listed on a Bittorrent tracker claiming to be the largest Bittorrent network on the Internet, instead of building small Bittorrent networks on testbeds such as PlanetLab and OneLab as other researchers have done. We also performed simulations using the same approach to show the validity of the inferred topology resulted from the PEX messages by comparing it with the topology of the simulated network. Our result, verified using the Kolmogorov-Smirnov goodness of fit test and the likelihood ratio test and confirmed via simulation, show that a power-law with exponential cutoff is a more plausible model than a pure power-law distribution. We also found that the average clustering coefficient is very low, implies the the Bittorrent swarms are close to random networks. Bittorrent swarms are far more dynamic than has been recognized previously, potentially impacting attempts to optimize the performance of the system as well as the accuracy of simulations and analyses.

In the current content delivery architecture, many CDN companies and ISPs adopt hybrid CDN-P2P because the advantage of P2P. In P2P side, peers are organized in a tree based overlay on a per substream basis for live streaming. This ensure that all peers contribute some upload bandwidth. Each CDN server keeps track of clients currently assigned to it to avoid undesirable side effects of P2P. Each client learns about other peers assigned to its designed CDN server. Since in hybrid CDN-P2P architecture some of workload or data delivery are done by peers, therefore CDN server foreseeing the potential power consumption reduction. Second problem to addressed in this research is what's the trade-off of hybrid CDN-P2P architecture compare to CDN. We solve this problem by proposing simple model of power consumption of CDN server and router including the cost of cooling that needed generated from power consumption of CDN server and router. Furthermore, this power reduction can be used for capacity planning of data center.

Finally, proposed methodology can contribute largely to further characterizing P2P networks and promotion of relaxing capacity planning data center in term of energy consumption by hybrid CDN-P2P.

Chapter 1

Introduction

1.1 Background

Internet-based multimedia content delivery enables users to watch desired content from any location at any point of time. With the increasing capacities of end-user devices and faster Internet connections, the popularity of such services is growing steadily. Cisco VNI predicts that video streaming will significantly outweigh other types of consumer Internet traffic, such as file sharing, Web, Voice over IP (VoIP), and online gaming [5]. Contrary to file transfers, video streaming enables users to watch the video while downloading it, which imposes strict requirements on the delivery infrastructure. The users expect a performance similar to the traditional television with short startup delays and without performance degradations or playback stalling during watching. This is exacerbated by the growing requirements on video quality, such as higher resolutions and additional features (high-definition and 3D videos). The higher quality typically results in increased video bitrates that require higher download bandwidth. Contrary to file transfers, video streaming enables users to watch the video while downloading it, which imposes strict requirements on the delivery infrastructure. The users expect a performance similar to the traditional television with short startup delays and without performance degradations or playback stalling during watching. This is exacerbated by the growing requirements on video quality, such as higher resolutions and additional features (high-definition and 3D videos). The higher quality typically results in increased video bitrates that require higher download bandwidth.

Today users are increasingly able to consume videos directly from their TV screens using Internet-enabled Set-top Boxes (STBs) such as digital video recorders, game consoles, or other entertainment devices. Questions arise as which delivery architecture is able to provide this vast amount of video content to end-user devices and which mechanisms are required to make this architecture scalable and cost-efficient. Common solutions are centralized and decentralized delivery architectures employing various mechanisms to deliver video streams to end-users. These delivery architectures build overlay networks on top of the underlying Internet infrastructure. The simplest architecture for video streaming is based on the centralized client-server model. Here (one or many) video servers send a separate video stream to each client, which results in high bandwidth costs for popular content and potential scalability issues for large numbers of concurrent users. The peer-to-peer (p2p) paradigm offers a promising alternative to pure server-based video distribution networks. Here, the users, called peers, not only consume but also provide services to other peers. The application of the p2p paradigm to video streaming uses peers' resources, such as local storage, computational power, and bandwidth, to reduce the load and costs of content servers. In the extreme case of pure p2p streaming, there are no dedicated servers anymore and all services are provided by regular peers. If we consider a commercial streaming system, a pure p2p solution turns out to be insufficient because it lacks important properties such as service guarantees for users, security, and control by the content provider. In order to overcome these limitations, a peer-assisted architecture can combine content servers and peers intelligently.

In order to understand the relationships between entities in P2P-CDN ecosystem and to identify the possible

tensions, we must understand their roles in the architecture:

- Overlay providers contribute the initial content and host servers for content injection and indexing. In a pure commercial scenario the overlay provider also acts as a content provider, while in a scenario with user-generated content the content is contributed by users that upload it to content servers. Typically, an overlay provider receives certain payments for the hosted content, either directly from users (usage-dependent or subscription-based) or indirectly via advertisements.
- Users consume the streamed videos but also provide their resources to the system, such as upload bandwidth, local storage space, and online time. The users typically pay flat-rate fees for the Internet access, which explains why they allow an overlay provider to use their upload bandwidth.
- Network operators provide infrastructure for Internet access and receive flat-rate payments from the users for this service. Typical delivery overlays span several network domains controlled by different network operators. Therefore, network operators must manage both the internal and external traffic flows to avoid congestion and excessive payments for traffic transit.

A peer-assisted solution shifts the main load of content delivery from the overlay providers servers to users. However, the actual delivery costs are shifted from the overlay providers to the network operators. The reason is the widespread acceptance of flat-rate based pricing for the Internet access. These pricing schemes allow network operators to attract users and to sell high-speed Internet connections. But peer-assisted overlays can also lead to bottlenecks and link congestions, since the Internet architecture is built for the client-server traffic pattern where the traffic flows from content servers to the users. In the last years, the management of overlay traffic that crosses the boundaries of network operators domains has gained a lot of attention in the research community. Thereby, various traffic management methods have been proposed to relieve the tension between the overlays and network operators. However, most of them fail to satisfy the demands of both parties.

1.2 Challenges

In this section, we discuss the specific challenges of peer-assisted. Most of these challenges arise from the necessity to achieve quality of service (QoS) comparable to the current client-server systems, while using the limited resources of unreliable peers.

- Limited resources of an individual peer compared to a typical server mean that the resources of many peers must be combined to serve the same streaming request. This applies in particular to the upload bandwidth, which is typically much smaller than the download bandwidth.
- Heterogeneity of peers in terms of their resources and behavior. For example, the upload capacity is a resource that differs between the users and affects the systems performance significantly.
- Lack of service guarantees at peers makes it difficult to ensure a quality streaming experience to the users (comparable to well-dimensioned server-based systems). In a commercial scenario, in contrast to pure p2p-based systems, all users should be able to receive the quality they paid for, which makes the coupling between the peers contribution of resources and received streaming quality undesirable.
- Missing or insufficient incentives for users to contribute their resources are a common issue for p2p-based systems. In a commercial scenario, it can be partially solved by offering rewards or discounts for contributed resources. For example, a peer might get certain credits for each megabyte of data uploaded to other peers. However, this does not solve the issue of users that should remain online in order to provide content availability.
- Energy consumption is becoming an important challenge for content delivery. While various approaches were proposed to increase the energy efficiency of servers and routers in terms of reduced power consumption, the same issue applies for the users devices. One interesting aspect here is whether an idle

peer should stay online to serve new requests or leave the system. While the first option would maximize the peers contribution to the system, the second option would save energy that might be wasted if the services of this peer are not required.

- Negative impact on the network infrastructure is another issue in peer-assisted and pure p2p delivery architectures. Most p2p and peer-assisted overlays apply their own application level routing mechanisms that might have undesired effects on the underlying network such as congested links or high costs for the transit traffic.

1.3 Motivation

P2P as in this case BitTorrent as the most popular filesharing applications dominated the Internet traffic and is still growing even though recent studies suggest that its growth is slower than the growth of Internet traffic and its proportion to the Internet traffic is declining. This popularity reflects the robustness and efficiency of the BitTorrent protocol. These characteristics of BitTorrent come from its peer and piece selection strategies to distribute large files efficiently.

Many properties of BitTorrent such as upload, download performance, peer arrival and departure have been studied but only few research have assessed the topological properties of BitTorrent. The BitTorrent system is different from other P2P systems. The BitTorrent protocol does not offer peer traversal and the BitTorrent tracker also does not know about the relationship between peers since peers never send information to the tracker concerning their connectivity with other peer. While a crawler can be used in other P2P networks such as Gnutella, in BitTorrent we can not easily use a crawler to discover topology, making direct measurement of the topology very difficult and challenging. This BitTorrent swarm topology reflects peer behavior. The peer relationship behavior is very important as a basis to design controllable P2P system that to be used together with other system for example peer assisted CDN or peer assisted cloud.

In the current modern content delivery, CDN providers tend to combine P2P with CDN in order to help the scaling the services, especially related to traffic or bandwidth saving. It has been done by for example: Akamai and Pando networks. The bigger issue is not traffic or bandwidth that is relatively easy to fulfill by adding network card into router or adding more servers, instead energy consumption by CDN provider itself inside data center. Since the Internet traffic grows, demand for scaling is also growing thus demand for energy is also growing. This growing is constrained by energy supply in data center. The usage of peer assisted CDN can be seen not only for helping scaling the services, but there is potential to reduce the energy consumption furthermore this reduction can relax energy budget inside data center.

1.4 Approach

The key factors in this research are: (1) characterization of peer dynamic in P2P systems and (2) energy consumption trade-off in the using of P2P to assist CDN server.

P2P Swarm Dynamics

The real-world BitTorrent swarms were measured using a rigorous and simple method in order to understand the BitTorrent topology. To our knowledge, our approach is the first to perform such a study on real-world the BitTorrent network topologies. We used the BitTorrent peer exchange (PEX) messages to infer the topology of BitTorrent swarms listed on a BitTorrent tracker claiming to be the largest BitTorrent network on the Internet, instead of building small BitTorrent networks on testbed such as PlanetLab or OneLab as other researchers have done. We also performed simulations using the same approach to show the validity of the inferred topology resulted from the PEX messages by comparing it with the topology of the simulated network.

Energy Consumption of peer assisted CDN

As an intermediate step in merging between P2P and CDN, this research introduces energy consumption trade-off in peer-assisted CDN. We analyze the characteristics and the requirements of peer-assisted CDN for live

streaming and peer-assisted CDN for online storage. Then we propose energy consumption model for both peer-assisted CDN architectures. To be able to validate the result, we use model from both architectures that currently running on the Internet which are LiveSky [54] and FS2you [11].

1.5 Contribution

This dissertation makes contributions for enabling analysis into integration of P2P services and CDN services.

- For P2P, we propose new and effective methodology to infer BitTorrent swarm topologies. We show that gathering BitTorrent swarm topologies is important as step to understand peer behavior.
- For energy trade-off, we show that both peer-assisted CDN architecture have different in energy characteristics that can be used as considering model in the service integration between P2P and CDN, furthermore this model can use by CDN provider as basis for: capacity planning in data center and incentive planning to customer who will run peer-assisted mode in home gateway.

Chapter 2

Related Work

Bittorrent protocol performance has been explored extensively [14] [23] [34] [43] [24] [55]. Although we know that the topology can have a large impact on performance, to date only a few papers have addressed the issue. Urvoy *et al.* [44] used a discrete event simulator to show that the time to distribute a file in a Bittorrent swarm has a strong relation to the overlay topology. Al-Hamra *et al.* [1], also using a discrete event simulator, showed that Bittorrent creates a robust overlay topology and the overlay topology formed is not random. They also show that peer exchange (PEX) generates a chain-like overlay with a large diameter. Dale *et al.* [7], in an experimental study on PlanetLab, show that in the initial stage of Bittorrent a peer will get a random peer list from the tracker. They found that a network of peers that unchoked each other is scale-free and the node degree follows a power-law distribution with exponent approximately 2. Dale *et al.* [7] also showed that the path length formed in Bittorrent swarms averages four hops and Bittorrent swarms have low average clustering coefficient. However, little work has been done on confirming that such controlled experiments correspond to the system.

We emphasize that compared to Hoßfeld *et al.* [16], our work provides a completely different approach and goal. Hoßfeld *et al.* [16] discuss the AS (Autonomous System) level topology of Bittorrent swarm for optimizing overlay traffic across ASes, while our study focus on microscopic dynamic aspect which is Bittorrent swarms topology itself (peer level or IP address level). The closest work to ours is Kryczka *et al.* [21]. While our method is somewhat similar to theirs, they focus on clustering and locality while our focus is on node degree and clustering. They use PEX to discover peer relationship, unfortunately they do not explain in detail how to process the PEX data set. Because of differing PEX implementations between Bittorrent clients, we need to be careful with it in data processing. In our work, we describe PEX behavior and its limitation on two popular Bittorrent clients: Vuze and uTorrent, and we also explain how to treat PEX data from different Bittorrent clients. We also provide simulation result to confirm that our methods for inferring peer relationship with PEX is valid. They observed that Bittorrent swarms have slightly higher clustering coefficient compared to random graphs of the same size and they observe neither Bittorrent swarm fulfills the properties of small world. The slightly difference in clustering come from the difference of PEX data processing. They assume that PEX is the same and complete for all Bittorrent clients, therefore they get slightly different results.

Our results agree with previous research [7] in some areas and disagree in others, perhaps for two reasons. First, power-law claims must be handled carefully. Many steps are required to confirm the power-law behavior, including alternative model checking, and we must be prepared for disappointment since other models may give a better fit. Second, our methodology relies on real work measurement combined with simulation for validation. This real-world measurement will reflect different types of clients connected to our swarm, and each client has a different behavior. We also face difficult-to-characterize network realities such as NAT and firewalls. Our ability to reproduce key aspects of the topology dynamics suggests that these factors have only limited impact on the topology, somewhat to our surprise.

Content Distribution Networks with peer assist have been successfully deployed on the Internet, such as Akamai [19] and LiveSky [54]. The authors of [19] conclude from two real world traces that hybrid CDN-P2P

can significantly reduce the cost of content distribution and can scale to cope with the exponential growth of Internet video content. Yin et al. [54] described LiveSkye as commercial operation of a peer-assisted CDN in China. LiveSky solved several challenges in the system design, such as dynamic resource scaling of P2P, low startup latency, ease of P2P integration with the existing CDN infrastructure, and network friendliness and upload fairness in the P2P operation. Measurement from LiveSky showed that LiveSky can save bandwidth around 40% [54]. The author in [18] and [17] proposed mechanisms to minimize CDN server bandwidth to make the content distribution cheap. They designed different peer prefetching policies of video on demand system in surplus mode while ensuring user quality of experience. A similar analysis has been done in [53] for live video streaming system where the authors proposed different limited peer contribution policies to reduce CDN bandwidth requirement and eventually off the distribution process from CDN to P2P system. An ISP friendly rate allocation schemes for a hybrid CDN-P2P video on demand system in [50]. These technique try to minimize CDN server bandwidth while reducing ISP unfriendly traffic and maximizing peer prefetching. Load on CDN server has been shown to be reduced using this approach while reducing cross ISP traffic. Above studies were performed for video on demand or live video streaming. While video is the most popular content, the systems can be also for other type contents. Moreover while content based services are growing, energy consumption of a content distribution system has not been analyzed.

Related to CDN and energy usage, in a seminal work [35], the authors show that if costs are based on electricity usage and if the power prices vary in real-time, global load balancing decision can be made such that users are routed to locations with the cheapest power without significantly impacting user performance or bandwidth cost. In [33], the author proposed utilizing batteries for CDN for reducing total supplied power and total power costs. The authors in [33] also proposed battery provisioning algorithms based on workload of CDN server. The result shows that batteries can provide up to 14% power savings.

The idea that utilize ISP controlled home gateway to provide computing and storage services and adopts managed peer-to-peer model is presented in [47]. Valancius et al. [47] show that distributing computing platform in NaDa (Nano Data Center) save at least 20-30% energy compare to traditional data centers. The saving in NaDa comes from underutilizing home gateway, avoidance of cooling costs, and the reduction of network energy consumption as a result of demand and service co-localization.

The comparison between CDN architecture and peer-to-peer architecture are discussed in [3] and [10]. Both authors in [3] and [10] agree that CDN architecture is more energy saving compare to peer-to-peer architecture. Another interesting study of energy efficient in content delivery architectures is presented by Guan et al. [13]. by Guan et al. [13] comparing energy efficient of CDN architecture and CCN architecture. The authors in [13] conclude that CCN is more energy efficient in delivering popular content while the approach with optical bypass is more energy efficient in delivering infrequent accessed content.

To the best of our knowledge, the study of energy in that considering peer-to-peer in CDN architecture is presented in [27]. Mandal et al. [27] mentioned that hybrid CDN-P2P systems can reduce a significant amount energy in the optical core network around 20-40% less energy. The authors only considered energy consumption of hardware especially optical devices and does not include overhead inside data center, CDN server energy consumption, and consumed power by peers. Our work is quite different, we take number of peers with static content and add overhead of data center which is power of cooling cause by temperature of hardware for different purpose which are live streaming and video on demand.

Chapter 3

P2P measurement

3.1 Introduction

BitTorrent as the most P2P filesharing application is responsible for a major portion of the Internet traffic share and is daily used by hundred of millions of users. This has attracted the interest of the research community that has thoroughly evaluated the performance and the demographic aspects of BitTorrent. Due to the complexity of the system, the most relevant studies have tried to understand different aspects by performing real measurements of BitTorrent swarms in the wild, this is inferring information from real swarms in real time. Several techniques have been used in order to measure different aspects of BitTorrent so far. In this Chapter we present a survey of different measurement techniques that constitutes a first step in the designing the future measurement techniques and tools for analyzing large scale systems.

3.2 Measuring BitTorrent

In this Section we describe the BitTorrent measurement techniques defined in the literature so far. We classify them into two main categories macroscopic and microscopic depending on the retrieved information.

3.2.1 Macroscopic Technique

The main objective of these techniques is to understand the demographics of the BitTorrent ecosystem: the type of published content, the popularity of the content, the distribution of BitTorrent users per country (or ISP), the relevance of the different portals and trackers, etc. Furthermore, the macroscopic measurements allow to study some performance aspects such as the ratio of seeders/leechers, the session time of the BitTorrent users, the arrival rate of peers, the seedless state (period the torrent is without seeder) duration, etc. We classify the macroscopic techniques into two subcategories: BitTorrent portals crawling and BitTorrent trackers crawling.

3.2.2 Microscopic Technique

The described macroscopic techniques retrieve exclusively the peers IP addresses, thus only metrics associated to the presence/absence of the peer can be studied. Unfortunately, IP address does not suffice to infer relevant performance metrics at the peer level such as peers download and upload rate. For this purpose we need to apply more sophisticated (but less scalable) techniques that we name microscopic techniques. To perform microscopic techniques we need to implement different parts of the BitTorrent peer wire protocol. Any microscopic crawler has to implement the functions to perform the handshaking procedure. This is essential to connect to other peers. The handshaking procedure can be done actively (the crawler initiates it) or passively (the crawler waits until a peer starts the handshaking). Once the crawler is connected to a peer, it exploits different messages of the peer wire protocol in order to measure different parameters.

Chapter 4

Characteristics of BitTorrent Swarms

4.1 Introduction

BitTorrent is one of the most used application in the current Internet and is responsible for an important portion of the upstream and downstream traffic as revealed by recent reports. The significant footprint of BitTorrent in the Internet has motivated researchers and practitioners to dedicate an important amount of effort to understanding and improving BitTorrent. However, despite this effort, we still have little knowledge regarding the connectivity properties exhibited by real BitTorrent swarms at both swarm and peer level. Due to the difficulty in collecting the required information from real swarms, most of the existing works that analyze connectivity properties are based on simulations or experiments in controlled environments. As a result, they are likely to miss some of the effects affecting BitTorrent swarms in the wild.

In this Chapter, we first present a methodology to collect the connectivity information at both the swarm and the peer level for the entire lifespan of a real torrent. Specifically, we discover new torrents just after their birth by using the RSS service of the most important BitTorrent portal, namely the Pirate Bay. Afterwards, we exploit the Peer Exchange (PEX) extension of the BitTorrent protocol to gather the set of neighbors for each peer. PEX is a gossiping technique which main goal is to allow peers to exchange their list of neighbors so that they can learn about other participants in the swarm without contacting the tracker. Note, that PEX has been implemented by most of the existing BitTorrent clients and in particular by the most popular ones such as uTorrent or Vuze. The information collected from PEX (i.e., a peers neighborhood) is the connectivity information at the peer level. Furthermore, by aggregating the neighborhood information collected from every peer in a swarm we are able to build the overlay topology of that swarm (i.e., swarm level connectivity). We retrieve the information from each active peer every 3 minutes and then study the dynamic evolution of both: the overlay topology of the swarm and the composition of each peers neighborhood. We have applied the described methodology to collect the connectivity information of 50 real torrents, including more than 150 peers, since their birth during a period of 10 days.

4.2 Measurement Methodology

The difficulties in inferring topologies in Bittorrent swarms are caused by the Bittorrent mechanism itself. First, although a Bittorrent *peer* may offer some information about its peers, there is no mechanism for peer *discovery*. Second, a peer never sends information about its connections with other peers to the tracker, so we cannot infer overlay topologies by querying or hosting a tracker. Our other options inferring topologies are simulation or deploying Bittorrent nodes in a real network or in a laboratory, e.g., PlanetLab. Deploying hundreds to thousands of nodes in a real network or in the laboratory in a manner that accurately reflects the real world is a very challenging task.

We used PEX to collect information about peer neighbors (see Fig.4.1), and then we describe the network

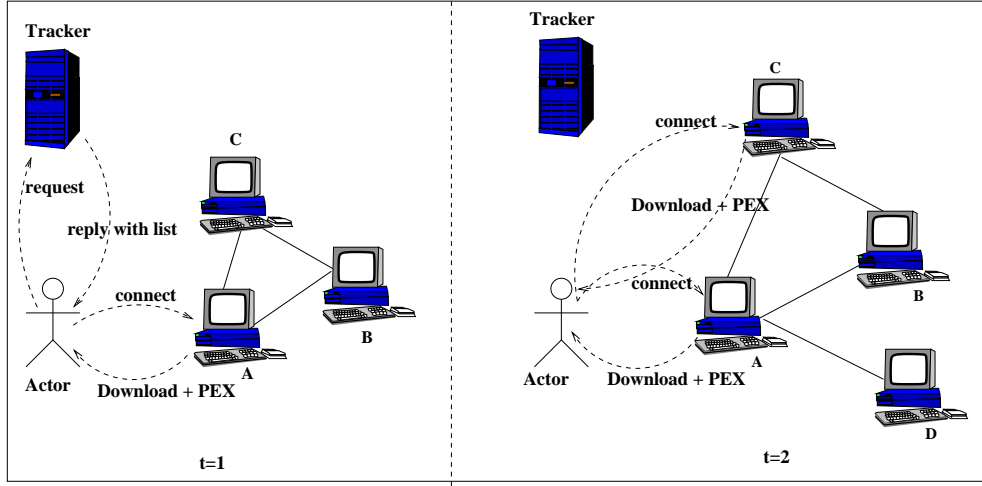

Figure 4.1: Simplified view of our approach. Left: At time $t=1$, the actor gets a PEX message from peer A and learns that peer A is connected to peer B and C. At $t=2$, the actor gets PEX messages from peers C and A. The actor learns that now peer A is connected to peer D. Thus the actor knows the properties of peer A at $t=1$ and $t=2$.

formed in terms of properties such as node degree and average clustering. Besides collecting data from real Bittorrent networks, we ran simulations similar to these of Al-Hamra *et al.* [2]. In these simulations, we assumed that peer arrivals and departures (churn) follow an exponential distribution as explained by Guo *et al.* [14]. For simplification, we assumed that nodes are not behind a NAT. Since we are only interested in the construction of the overlay topology, we argue that our simulations are thorough enough to explain the overlay properties.

Temporal graphs have recently been proposed to study real dynamic graphs, with the intuition that the behaviour of dynamic networks can be more accurately captured by a sequence of snapshots of the network topology as it changes over time [12] [42]. In highly dynamic networks such as P2P, an instantaneous snapshot may capture only a few nodes and links. In this paper, we study the network dynamics by continuously taking network snapshots over a short time interval Δ , and show them as a time series. A snapshot captures all participating peers and their connections within a particular time interval, from which a graph can be generated. The snapshot duration may have minor effects on analyzing slowly changing networks. However, in a P2P network, the characteristics of the network topology vary greatly with respect to the time scale of the snapshot duration [39]. We consider $\Delta = 3$ minutes to be a reasonable estimate of minimum session length in Bittorrent [37].

4.2.1 Graph Sampling

Due to the large and dynamic nature of Bittorrent networks, it is often very difficult or impossible to capture global properties. Facing this difficulty, sampling is a natural approach. However, collecting unbiased or representative sampling is also sometimes a challenging task.

Suppose that a Bittorrent overlay network is a graph $G(V, E)$ with the peers or nodes as vertices and connections between the peers as edges. If we observe the graph in a time series, i.e., we take samples of the graph, the time-indexed graph is $G_t = G(V_t, E_t)$. From this set of graphs, we can define a measurement window $[t_0, t_0 + \Delta]$ and select peers uniformly at random from the set: $V_{t_0, t_0 + \Delta} = \bigcup_{t=t_0}^{t_0 + \Delta} V_t$. In that equation, we cannot distinguish properties of the same peer at different times, thus it focuses on sampling peers instead of peer properties. Stutzbach *et al.* [38] showed that equation is only appropriate for exponentially distributed peer session lengths but we know from existing measurement that Bittorrent networks peer session lengths have very high variation [14].

For example: suppose we want to measure number of files shared by peers in Bittorrent swarm. In this

Bittorrent swarm, half of the peers are up all the time and have many files, while other peers remain around for one minute and are immediately replaced by new short-lived peers who have few files. The common method is to observe the system for a long time and sample the peers randomly. This method will incorrectly conclude that most of the peers in the system have very few files. The problem with this method is that it focuses on sampling the number of peers instead of peer properties. Our objective should not be to select a vertex $v_i \in \bigcup_{t=t_0}^{t_0+\Delta} V_t$, but to sample the property of a vertex v_i at a particular instant time t . Therefore, we must distinguish the occurrences of the same peer at different times: samples $v_{i,t}$ and $v_{i,t'}$ gathered at different times $t \neq t'$ are viewed as different, even from the same peer. The key in this method is that we must be able to sample from the same peer more than once at different points in time. Thus we can formalize this into $v_{i,t} \in V_t, t \in [t_0, t_0 + \Delta]$ [38]. With that method, the sampling will not be biased because we track the peer's properties overtime.

The number of peers in a swarm that is observed by our client is our population. The sampled peers set is the number of peers that exchange PEX messages with our client. Our sampled peers set through PEX messages exchange can observe about 70% of the peers in a population. This observation is consistent with [52].

4.2.2 Experimental Methodology

We joined the top 50 TV series torrents from the piratebay, which claims to be the biggest torrent tracker on the Internet. Almost all of these torrents were in steady-state phase, which is more dominant than the bootstrapping and decay phases of a torrent's lifetime. We used a modified rasterbar libtorrent [31] client that is connection greedy, where the client tries to connect to all peers it knows without a limit on the number of connections, and the client logs PEX messages received from other clients. PEX messages from old versions of Vuze Bittorrent clients contain all of peers they connected to in the past, hence these clients should be removed from the data. Removal of some peers in data processing is valid in terms of sampling with dynamics, see Sect.(4.2.1). In terms of connectivity, two popular Bittorrent clients (uTorrent and Vuze), by default try to connect to peer candidates randomly without any preference, thus we have random data sets. This implies that our data set is independent of measurement location and the number of measurement locations.

4.2.3 Data Analysis Background

Many realistic networks exhibit the scale-free property [6], though we note that "scale-free" is not a complete description of a network topology [9] [26]. It has been suggested that Bittorrent networks also might have scale-free characteristics [7]. In this paper, we test this hypothesis. Besides testing this hypothesis, we also study the clustering property of Bittorrent swarms.

In a scale-free network, the degree distribution follows a power-law distribution. A power-law distribution is quite a natural model and can be generated from simple generative processes [28], and power-law models appear in many areas of science [6] [28].

A power-law distribution can be described as:

$$Pr[X \geq x] \propto cx^{-\alpha}. \quad (4.1)$$

where x is the quantity of distribution and α is commonly called the scaling parameter. The scaling parameter usually lies in the range $1.8 < \alpha < 3.5$. In discrete form, the above formula can be expressed as:

$$p(x) = Pr(X = x) = Cx^{-\alpha}. \quad (4.2)$$

This distribution diverges on zero, therefore there must be a lower bound of x , called $x_{min} > 0$, that holds for the sample to be fitted by a power-law. If we want to estimate a good power-law scaling parameter then we must also have a good x_{min} estimation.

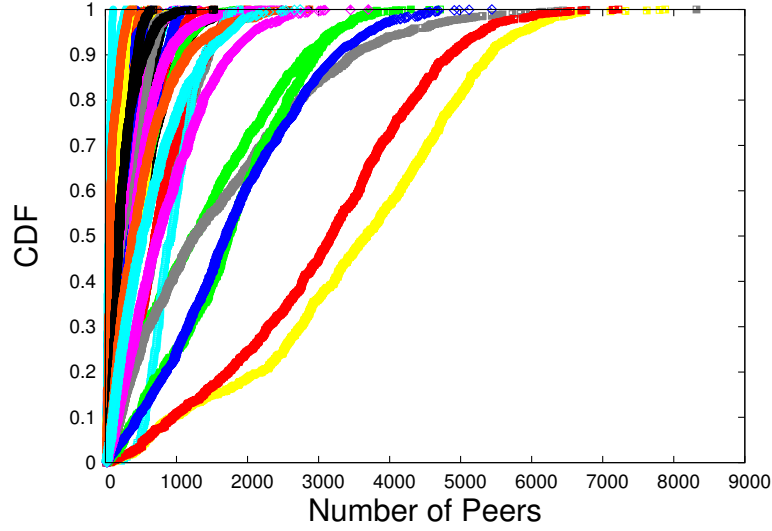

Figure 4.2: CDF plot of number of peers for the 50 swarms during measurement.

Normalizing (4.2) we get

$$p(x) = \frac{x^{-\alpha}}{\zeta(\alpha, x_{min})}. \quad (4.3)$$

The most common way to fit empirical data to a power-law is to take the logarithm of Eq.(4.1) and draw a straight line on a logarithmic plot [28]. We use maximum likelihood to estimate the scaling parameter α of power-law [6]. This approach is accurate to estimate the scaling parameter in the limit of large sample size. For the detailed calculations of both x_{min} and α , see Appendix B in [6].

4.3 Experimental Results

Our time samples for the size of swarms are plotted as the CDF of the number of peers for every swarm during measurement with 104 to 1400 time samples for each torrent, as shown in Fig.4.2. It is clear that the number of peers has high variability due to churn in Bittorrent networks.

4.3.1 Power-law Distribution of Node Degree

The degree of a node in a network is the number of edges connected to that node. If we define p_k as the fraction of nodes in the network that have degree k , then p_k is the probability that a node chosen uniformly at random has degree k . We show node degree data in cumulative distribution function (CDF) plot, which can be expressed as

$$P_k = \sum_{k'=k}^{\infty} p_{k'}. \quad (4.4)$$

We want to know the power-law distribution of the measured Bittorrent networks, and we do not know *a priori* if our data are power-law distributed. To test the applicability of a power-law distribution, we use the goodness-of-fit test as described by Clauset *et al.* [6]. First, we fit data to the power-law model and calculate the Kolmogorov-Smirnov (KS) statistic for this fit. Second, we generate power-law synthetic data sets based on the scaling parameter α estimation and the lower bound of x_{min} . We fit the synthetic data to a power-law model and calculate the KS statistics, then count what fraction of the resulting statistics is larger than the value for the measured data set. This fraction is called the p value. If $p \geq 0.1$ then a power-law model is a good model for the data set, and if $p < 0.1$ then power-law is not a good model.

Figure 4.3: Node degree fit for snapshots of two torrents, with three fits shown in log scale.

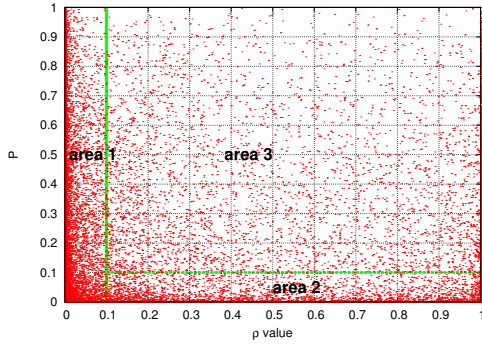

Figure 4.4: CDF plot of p value of K-S statistics.

As mentioned before, a good estimation for x_{min} is important to get a overall good fit. Too small an x_{min} will cause a fit only to the body of the distribution. Too high an x_{min} will cause a fit only to the tail of the distribution. Figure 4.3 illustrates the fit for snapshots of *torrent1* and *torrent3*. For *torrent1*, setting $x_{min} = 2$ leads to $\alpha = 2.11$, while $x_{min} = 1$ gives $\alpha = 2.9$. For *torrent1*, $x_{min} = 1$ visually does not give a good fit, while for *torrent3*, setting $x_{min} = 1$ leads to a visually good fit.

Figure 4.4 shows the CDF for p values for all data sets. This figure shows that from the K-S statistics point of view, around 45% of the time a power-law distribution is not a good fit for the data. The inset figure in Fig.4.4 shows the CDF plot p value for each torrent. The dash line on p value = 0.1 is the threshold.

However, these data sets must be interpreted with care. The usage of the maximum likelihood estimators for parameter estimation in power-law is guaranteed to be unbiased only in the asymptotic limit of large sample size, and some of our data sets fall below the rule of thumb for sample size, $n = 50$ [6]. In the goodness-of-fit test, a large p value does not mean the power-law is the correct distribution for data sets, because there may be other distributions that match the data sets and there is always a possibility that even with small value of p the distribution will follow a power-law [6]. We address these concerns next.

Figure 4.5: Scatter plot of p value vs ρ value.Figure 4.6: Scatter plot of p value vs log-likelihood ratio (LR) for $\rho < 0.1$.

4.3.2 Alternative Distributions

Even if we have estimated the power-law parameter properly and the fit is decent, it does not mean the power-law model is good. It is always possible that non-power-law models are better than the power-law model. There are several methods for direct comparison of two distributions such as *likelihood ratio test* [49], *Bayesian test*, and *Minimum description length*. The likelihood ratio test idea is to compute the likelihood of the data sets under two distributions. The one with the higher likelihood is the better fit. We use the likelihood ratio test to see whether other distributions can give better parameter estimation.

Nested Case

We now hypothesize that the smaller family of power-law distributions may give a better fit to our data sets. We only consider a power-law model and a power-law with exponential cut-off model as examples to show model selection. Model selection for power-law model and power-law with exponential cut-off is a kind of nested model selection problem. In a nested model selection, there is always the possibility that a bigger family (power-law) can provide as good a fit as the smaller family (power-law with exponential cut-off). In a likelihood ratio test, we must provide the significance value (ρ value). Under the likelihood ratio test, we compare the pure power-law model to power-law with exponential cut-off, and the ρ value here helps us establish which of three possibilities occurs: (i) $\rho > 0.1$ means there is no significant difference between the likelihood of the data under the two hypotheses being compared and thus neither is favored over the other; if we already rejected the pure power-law model, then this does not necessarily tell us that we also can reject the alternative model; (ii) $\rho < 0.1$ and the sign of likelihood ratio (LR) = negative means that there is a significant difference in the likelihoods and that the alternative model is better; if we have already rejected the pure power-law model, then this case simply tells us that the alternative model is better than the bad model we rejected; (iii) if $\rho < 0.1$ and the sign of LR = positive means that there is a significant difference and that the pure power-law model is better than the alternative; if we have already rejected the pure power-law model, then this case tells us the alternative is even worse than the bad model we already rejected.

Figure 4.5 shows a p value vs ρ value scatter plot, divided into three areas. Area 1: $\rho < 0.1$ and $p > 0$. Area 2: $\rho > 0.1$ and $p < 0.1$. Area 3: $\rho > 0.1$ and $p > 0.1$. This figure shows that 52% of the samples lie in area 1, thus an alternative model may be plausible for these samples.

Now we plot p value vs LR as shown in Fig.4.6 for $\rho < 0.1$. We divide the figure into four areas: area 1, area 2, area 3, and area 4 with green lines as borders to see how sparse the points are in each area. Area 1: LR=positive sign and $p < 0.1$. Area 2: LR=positive sign and $p > 0.1$. Area 3: LR=negative sign and $p < 0.1$. Area 4: LR=negative sign and $p > 0.1$. In this figure, 58% of the samples lie in area 3 and 42% lie in area 4, while there are no samples in areas 1 and 2, which means that the alternative model is better. Although in the case $p < 0.1$ we reject power-law as the plausible model, the alternative model is still better than the power-law model. We believe that these results are caused by peers that are not willing to maintain large numbers of

Figure 4.7: CDF plot of ρ value of log-likelihood ratio test for power-law v.s log-normal.

Figure 4.10: Scatter plot p values v.s log-likelihood ratio (LR) for likelihood test for power-law vs exponential.

concurrent connections (high node degree). These observations clearly demonstrate that comparing models is a very complex task in highly dynamic networks.

Non-Nested Case

In the non-nested case, we compare power-law distribution with log-normal distribution and exponential distribution. We calculate the ratio of two likelihood distributions or the logarithm of the ratio, which is positive or negative depending on which distribution is better. The positive or negative sign of log-likelihood ratio does not definitively indicate which model is the better fit. Vuong's [49] method gives a ρ value that can tell us whether the observed sign of likelihood ratio is statistically significant. If this ρ value is small ($\rho < 0.1$) then the sign of log-likelihood ratio is a reliable indicator of which model is the better fit to the data. If the ρ value is large the sign of log-likelihood ratio is not reliable and the test does not favor either model over the other.

Figure 4.7 and Fig.4.9 show the CDF of the ρ value for the log-likelihood ratio between power-law and log-normal distributions and the log-likelihood ratio between power-law and exponential distributions. Both alternative distributions only show very small number of data points that have $\rho < 0.1$, each at around 13% and 5.5%. The log-likelihood ratio of these data points have negative signs as shown in Fig.4.8 and Fig.4.10, therefore the alternative distributions are not better than power-law. With the vast majority of the values for ρ being larger than 0.1, the results of the log-likelihood ratio test are ambiguous. Therefore, it is important to look at theoretical factors or design factors behind the systems to make a sensible judgment. For example: a leecher in a Bittorrent swarm is design to prefer the fastest seeders or leechers instead of high degree seeders or leechers. With this design factor information, we can make a sensible judgment which distributional form is more reasonable.

Figure 4.11: CDF plot of the clustering coefficient for each torrent.

4.3.3 Clustering Coefficient

Networks show a tendency for link formation between neighboring vertices called *clustering* that reflects the topology robustness. The clustering around a vertex i is quantified by the clustering coefficient C_i , defined as the number of triangles in which vertex i participates normalized by the maximum possible number of such triangles,

$$c_i = \frac{2t_i}{k_i(k_i - 1)} \quad (4.5)$$

where t_i denotes the number of triangles around i and k_i denotes vertex degree. For the whole graph, the clustering coefficient is

$$C = \frac{1}{n} \sum_{i \in G} c_i. \quad (4.6)$$

A larger clustering coefficient represents more clustering at nodes in the graph, therefore the clustering coefficient expresses the local robustness of the network. The distinction between a random and a non-random graph can be measured by clustering-coefficient metrics [51]. A network that has a high clustering coefficient and a small average path length is called a *small-world* model [51]. In Bittorrent systems, a previous study [22] mentioned the possibility that Bittorrent's efficiency partly comes from the clustering of peers. Figure 4.11 shows the CDF clustering coefficient value of our data sets. Only one torrent exhibits clustering coefficient less than 0.1 for about 40% of the snapshots, while for the other torrents, more than 70% are less than 0.1. This low clustering coefficient observation is the same as that observed by Dale *et al.* [7]. Considering only the low clustering coefficient, the Bittorrent topologies seem to be close to random graphs.

4.4 Confirmation via Simulation

We use simulations to compare the overlay topology properties based on our real-world experiments. We set the maximum peer set size to 80, the minimum number of neighbors to 20, and the maximum number of outgoing connections to 80. In our simulation, the results are quite easy to get since we are on a controlled system; we can directly read the global topology properties from our results. We also have the simulated PEX messages. We compare the global overlay topology properties as the final result from the simulator with the overlay topology that we get from PEX on the same simulator. Figure 4.12 shows the α estimate Eq.(4.1) and p Eq.(4.1) value

Figure 4.12: α estimation and p value for global topology and topology inferred from PEX where both done in our simulator.

both for the global result and the PEX result from our simulator. It clearly shows that both the global result and the PEX result from the simulator produce very low p values. We calculate the Spearman correlation for both α values from the global result and the PEX result. The Spearman rank correlation coefficient is a non-parametric correlation measure that assesses the relationship between two variables without making any assumptions of a monotonic function. The Spearman rank correlation test gives $0.38 \leq \rho \leq 0.5$, which we consider to be moderately well correlated. Therefore, the simulator confirms that the PEX method can be used to estimate α .

4.5 Related Work

Bittorrent protocol performance has been explored extensively [14] [23] [34] [43] [24] [55]. Although we know that the topology can have a large impact on performance, to date only a few papers have addressed the issue. Urvoy *et al.* [44] used a discrete event simulator to show that the time to distribute a file in a Bittorrent swarm has a strong relation to the overlay topology. Al-Hamra *et al.* [1], also using a discrete event simulator, showed that Bittorrent creates a robust overlay topology and the overlay topology formed is not random. They also show that peer exchange (PEX) generates a chain-like overlay with a large diameter. Dale *et al.* [7], in an experimental study on PlanetLab, show that in the initial stage of Bittorrent a peer will get a random peer list from the tracker. They found that a network of peers that unchoked each other is scale-free and the node degree follows a power-law distribution with exponent approximately 2. Dale *et al.* [7] also showed that the path length formed in Bittorrent swarms averages four hops and Bittorrent swarms have low average clustering coefficient. However, little work has been done on confirming that such controlled experiments correspond to the system.

We emphasize that compared to Hoßfeld *et al.* [16], our work provides a completely different approach and goal. Hoßfeld *et al.* [16] discuss the AS (Autonomous System) level topology of Bittorrent swarm for optimizing overlay traffic across ASes, while our study focus on microscopic dynamic aspect which is Bittorrent swarms topology itself (peer level or IP address level). The closest work to ours is Kryczka *et al.* [21]. While our method is somewhat similar to theirs, they focus on clustering and locality while our focus is on node degree and clustering. They use PEX to discover peer relationship, unfortunately they do not explain in detail how to process the PEX data set. Because of differing PEX implementations between Bittorrent clients, we need to be careful with it in data processing. In our work, we describe PEX behavior and its limitation on two popular Bittorrent clients: Vuze and uTorrent, and we also explain how to treat PEX data from different

Bittorrent clients. We also provide simulation result to confirm that our methods for inferring peer relationship with PEX is valid. They observed that Bittorrent swarms have slightly higher clustering coefficient compared to random graphs of the same size and they observe neither Bittorrent swarm fulfills the properties of small world. The slightly difference in clustering come from the difference of PEX data processing. They assume that PEX is the same and complete for all Bittorrent clients, therefore they get slightly different results.

Our results agree with previous research [7] in some areas and disagree in others, perhaps for two reasons. First, power-law claims must be handled carefully. Many steps are required to confirm the power-law behavior, including alternative model checking, and we must be prepared for disappointment since other models may give a better fit. Second, our methodology relies on real work measurement combined with simulation for validation. This real-world measurement will reflect different types of clients connected to our swarm, and each client has a different behavior. We also face difficult-to-characterize network realities such as NAT and firewalls. Our ability to reproduce key aspects of the topology dynamics suggests that these factors have only limited impact on the topology, somewhat to our surprise.

4.6 Summary

We have investigated the properties of Bittorrent overlay topologies from the point of view of the peer exchange protocol using real swarms from an operational Bittorrent tracker on the Internet.

We find that the node degree of the graph formed in a Bittorrent swarm can be described by a power law with exponential cut-off and the observation of a low clustering coefficient implies Bittorrent networks are close to random networks. From the Bittorrent protocol point of view, the reason that a Bittorrent swarm can be described by a power-law with exponential cut-off is: leechers in a Bittorrent swarm prefer a few good seeders or neighbors that can give high data rates to exchange the data and seeders have rich connections to leechers as seeders have complete chunks or pieces. That behavior explains why seeders have rich connections while leechers only have a few neighbors. We argue that there are two reasons for the cut-off phenomenon. First, most Bittorrent clients configure the maximum number of global connection between 200 – 300, however the maximum connection per torrent (swarm) is set between 50 – 90 by default [36] [46]. Some Bitorrent forums suggest decreasing the maximum connection for torrent (swarm) to between 30 – 40 [45]. Second, most of the Bittorrent users are home users where their home gateway device cannot give high concurrent connections and Bitorrent is not the main online activity. We argue that the Bittorrent swarm closes to random that we infer from clustering coefficient is caused by Bittorrent mechanism itself that always choose random peers from its neighbors in the choking-unchoking algorithm, optimistic choking algorithm, and optimistic connect algorithm as we explained previously. Our approach can infer BitTorrent swarms topology and the result confirmed by simulation.

Chapter 5

Green Networking

Since the seminal paper by Gupta and Singh [15], presented at SIGCOMM in 2003, the subject of green networking has received considerable attention. In recent years, valuable efforts have been devoted to reducing unnecessary energy expenditure. Big companies such as Google, Microsoft, and Amazon, are turning to a host of new technologies to reduce operating costs and consume less energy. Google, for example, is planning to operate its data centers with a zero carbon footprint by using, among other things, hydropower, water-based chillers, and external cold air to do some of the cooling. Several approaches have been considered to reduce energy consumption in networks. These include:

- The design of low power components that are still able to offer acceptable levels of performance. For example, at the circuit level techniques such as Dynamic Voltage Scaling (DVS) and Dynamic Frequency Scaling (DFS) can be used. With DVS the supply voltage is reduced when not needed, which results in slower operation of the circuitry. DFS reduces the number of processor instructions in a given amount of time, thus reducing performance. These techniques can reduce energy consumption significantly.
- Consuming energy from renewable energy sources sites rather than incurring in electricity transmission overheads, thus reducing CO₂ emissions.
- Designing new network architectures, for example by moving network equipment and network functions to strategic places. Examples include placing optical amplifiers at the most convenient locations and performing complex switching and routing functions near renewable sources.
- Using innovative cooling techniques. Researchers in Finland, for instance, are running servers outside in Finnish winter, with air temperatures below 20 degrees celsius.
- Performing resource consolidation, capitalizing on available energy. This can be done via traffic engineering, for instance. By aggregating traffic flows over a subset of the network devices and links allows others to be switched off temporarily or be placed in sleep mode. Another way is by migrating computation, typically using virtualization to move workloads transparently.

Chapter 6

Energy Saving in Peer-Assisted CDN

6.1 Motivation

Streaming content, especially video, represents a significant fraction of the traffic volume on the Internet, and it has become a standard practice to deliver this type of content using Content Delivery Networks (CDNs) such as Akamai and Limelight for better scaling and quality of experience for the end users. For example, YouTube uses Google cache and MTV uses Akamai in their operations.

With the spread of broadband Internet access at a reasonable flat monthly rate, users are connected to the Internet 24 hours a day and they can download and share multimedia content. P2P (peer to peer) applications are also widely deployed. In China, P2P is very popular; we see many P2P applications from China such as PPLive, PPStream, UUSe, Xunlei, etc. [48]. Some news broadcasters also rely on P2P technology to deliver popular live events. For example, CNN uses the Octoshape solution that enables their broadcast to scale and offer good video quality as the number of users increases [32].

From the Internet provider point of view, the presence of so many always-on users suggests that it is possible to delegate a portion of computing, storage and networking tasks to the users, thus creating P2P networks where users can share files and multimedia content. Starting from file sharing protocols, P2P architectures have evolved toward video on demand and support for live events.

CDN architectures are host-oriented: content is delivered to end users through host servers that are centrally managed in a few data centers fig.6.1. The growing of Internet traffic dominated by video, the energy consumption of a host oriented architecture becomes problematic due to over provisioning factor. The idea of utilizing the user's computation power to support ISP operation is not new. The figaro project proposed residential gateway as an integrator of different networks and services, becoming an Internet wide distributed content management for a proposed future Internet architecture. The important key in this architecture is both user home gateway and access bandwidth controlled and managed by ISP.

An overlay providers main goal in utilizing an home gateway delivery network is to save bandwidth and to reduce hosting costs of its servers. Additionally, this approach reduces the cooling costs of the servers that make up a large part of hosting costs. The reduction of server costs (without a performance degradation) requires that users contribute sufficient amount of resources. These resources include the upload bandwidth, CPU, memory, disk storage, and last but not least their online time. As Internet access is typically paid in a flat-rate manner, the additional upload of video segments might not result in additional costs for the users. The requirements of CPU, memory, and disk storage are also comparably low, since the uploaders dont need to render or re-encode the videos. Instead, the only requirement is to forward video segments to other receivers.

In this case, ISP can offload part of workload on their CDN to user's home gateway. By offloading workload, their CDN can relax energy demand thus relaxing data center power budget or relaxing capacity planning for power. This architecture depends largely on the number of devices which can be found online at a point in time. While some users keep their home gateway online at all times, there are small number of users might turn off

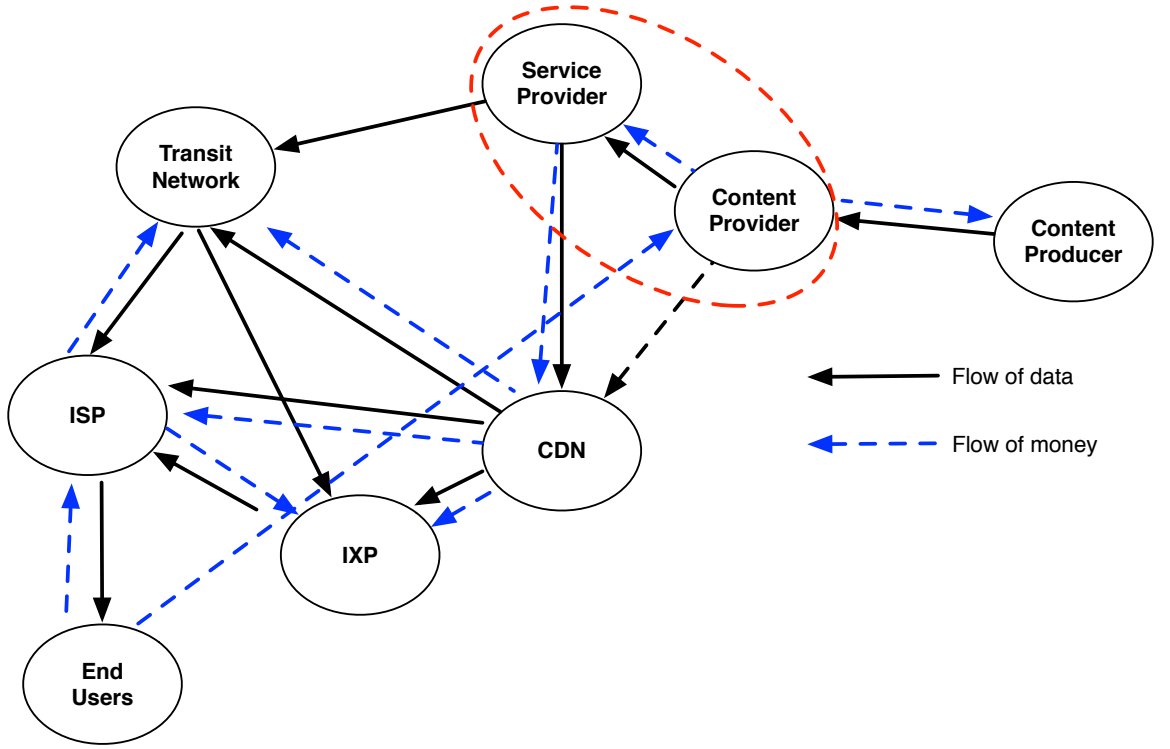

Figure 6.1: In Complex relationship of entities in Internet, CDN mostly placed in data center near to eyeball ISP. If CDN can not reach eyeball ISP due to business or economic reason, CDN can be placed near to IXP or even inside IXP, and CDN will reach eyeball ISP from peering point inside IXP.

or their home gateway can not be reached. Based on study from Dischinger et al., [8] and Valancius et al., [47], the average availability of the residential gateways in 12 major ISPs over one month is up 85% with 5% until 8% uptime variations thought out a day.

In this chapter, we presents our work on tradeoff of power consumption of CDN-P2P architecture.

6.2 System Description

Figure 6.2 shows model of CDN with peer assisted. P_s in fig.6.2 is peers in level 1 or seeders. Seeders get content directly from CDN. P_l in fig.6.2 is peers in level 2 or leechers. Leechers get content from seeders.

Maximum number of seeders is bounded by maximum CDN's capacity, while maximum number of leechers in level 2 is bounded by number of seeders can support the bitrate. Denote number of seeders is n_s , number of leechers is n_l , ρ is maximum bitrate that supplied by seeders to leechers, and $r = 1$ is video bitrate, therefore we have number of leechers that can be supported by seeders is:

$$\lfloor n_l \rfloor = n_s \cdot \rho \quad (6.1)$$

Number of seeders that support or upload content to leecher is:

$$n_s^u = n_l \cdot \frac{r}{\rho} \quad (6.2)$$

The illustration as follows, suppose we have video bitrate $r = 1$, seeder upload rate $\rho = 0.25$, and maximum

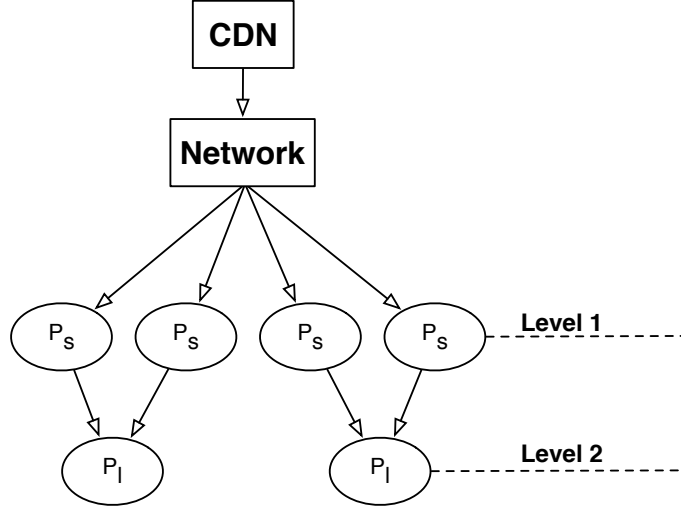

Figure 6.2: Model of content delivery architecture with peer assisted.

CDN capacity is $643Mbps$. Maximum number of seeders supported by CDN is $n_s = 643$. Maximum number leechers supported by seeders is $n_l = 160$. Number of seeders that upload content to leechers is $n_s^u = 640$. Therefore we have three seeders that do not need to upload content to leecher.

6.2.1 Abstracting Data Center Power

However, the COP for a cooling cycling is not constant, increasing with the temperature of the air the cooling unit pushes into the plenum. COP value empirically can be computed using [29]:

$$COP(T) = 0.0068.T^2 + 0.0008.T + 0.458 \quad (6.3)$$

where $T = T_{sup} + T_{adj}$ and $T_{adj} = T_{safe}^{in} - T_{max}^{in}$.

T_{sup} is temperature supply by cooling unit and T_{adj} is temperature difference between maximum safe hardware inlet temperature (T_{safe}^{in}) and the maximum observed hardware inlet temperature (T_{max}^{in}). If T_{adj} is negative, it indicates that a hardware inlet exceeds maximum safe temperature thus we need to lower T_{sup} to bring the hardwares back below the system redline level.

Cooling cost can be calculated as [29] :

$$C = \frac{Q}{COP(T)} \quad (6.4)$$

Where Q is amount of power the servers and hardwares consume. $COP(T)$ is our COP at $T = T_{sup} + T_{adj}$. Currently we assume a uniform T_{sup} from each cooling units due to the complications introduced by non-uniform cold air supply.

6.2.2 Energy Model

In this paper, our goal is to provide a general view and a fair comparison of the energy consume by a CDN and hybrid CDN-P2P architecture. To do so, we designed a series of model and perform an analysis. Our energy model is similar to the models used in [30]. Network model for energy is assumed to be flat network as shown in fig.6.2.

Figure 6.3: COP curve for the chilled water cooling units from HP Lab utility data center. As the target temperature of the air the cooling unit pumps into the floor plenum increases, the COP increases.

For each component, we consider two energy measurement: baseline energy consumption and energy consumed per work unit δ . The baseline energy is the energy consumed to keep the device on. Even when there is no traffic, the device still consume energy. The energy consumption for a single request in CDN server as:

$$E_d = E_s \quad (6.5)$$

while the energy consumption for a single request in network as:

$$E_r = d_s \cdot E_r \quad (6.6)$$

and energy of peer or client is E_p .

where d_s is number of hops or the path length. We define δ_s and δ_r work-induced energy consumed per additional bit transferred by a server and router. We can express these per-bit work induced consumptions as follows:

$$\delta_s = \frac{(S_{max} - S_{base})}{M_s} \quad (6.7)$$

S_{base} is a server's baseline power consumption. S_{max} is a server's power when operating at maximum capacity. M_s is the maximum capacity in bit per second for a server. Same formulation also applied for network component.

$$\delta_r = \frac{(R_{max} - R_{base})}{M_R} \quad (6.8)$$

R_{max} is a router power when operating at maximum capacity. R_{base} is a router's baseline power consumption. M_R is maximum capacity in bit per second for a router.

Substituting eq.6.7, and eq.6.8 to eq.6.5 and eq.6.6, we can rewrite eq.6.5 and eq.6.6 as follows:

$$\begin{aligned} E_d &= \delta_s \cdot B + E_{s-baseline} \\ E_r &= d_s \cdot \delta_r \cdot B + E_{r-baseline} \\ E_p &= \delta \cdot B + E_{p-baseline} \end{aligned} \quad (6.9)$$

Finally total energy is:

$$\begin{aligned} E_t &= E_d + E_r + E_p \\ E_t &= \delta_s \cdot B + E_{s-baseline} + d_s \cdot \delta_r \cdot B + E_{r-baseline} + \delta_p \cdot B + E_{p-baseline} \end{aligned} \quad (6.10)$$

where B is size of file to be transferred.

Considering cooling energy, we can substitute eq.6.4 to eq.6.10, therefore total energy consumed:

$$\hat{E}_t = E_t \cdot \left(1 + \frac{1}{COP(T)} \right) \quad (6.11)$$

6.3 Result and Discussion

6.3.1 Live Streaming

For numerical simulation, we use work induced energy consumed per second from [30]. For CDN server baseline, we use server idle power $E_{s-baseline} = 290$ watt and router baseline power $E_{r-baseline} = 750$ watt [30]. For peer baseline, we use peer base power $E_{p-baseline} = 13.5$ watt [47]. The peer has 256MB flash storage. The data flows from CDN to network in this case router then arrive in seeders. If seeders need to upload data to leechers then, it will flows through router then arrive in leechers. Parameters values used in this numerical simulation is shown in table 6.1.

Table 6.1: Numerical Simulation Parameters.

Symbol	Value
δ_s	$5.2 \cdot 10^{-8}$ (J/b)
δ_r	$8.0 \cdot 10^{-9}$ (J/b)
δ_p	$16 \cdot 10^{-9}$ (J.b)
$E_{r-baseline}$	750 watt
$E_{s-baseline}$	290 watt
$E_{p-baseline}$	13.5 watt
d_s	1
N_s^u	[0.25, 0.5, 0.75, 1] Mbps
N	[100, ..., 1000]
T	[20, 25] correspond to COP value [3.194, 4.728]

Figure 6.5 shows energy usage for CDN server, router, total energy consumption for CDN scenario (without peer assisted). We plot energy consumption for CDN server, router, clients, and total energy for every T or COP coefficient value. In CDN only scenario, the energy consumption is increase as number of client increase. This is natural because increasing of clients imply to increasing of traffic from CDN server through router to clients. The effect of different T to total energy is small. It is between 1% until 7.7%.

Figure 6.6 shows energy consumption for CDN, router, and total energy consumption for CDN-P2P scenario. We use upload rate of seeders to leechers $\rho = 0.25$. We assume that CDN server always utilize under 50%. For CDN server energy E_d , the usage of energy increase until number of seeders $n_s = 500$. On $n_s = 500$ the CDN server right on 50% utilization. When CDN server on 50% utilization, maximum number of seeders are $n_s = 500$ and number of leechers can be served by seeders is 125 peers. Therefore in this situation, CDN server can save energy, because with just 50% utilization, additional 125 peers are served from seeders. We can see this situation as flat line in fig.6.6. Next, to be able to server more peers, we allow CDN server to increase the 62.5% utilization. With 62.5% utilization, 625 peers served by CDN server. Number of leechers can be supported by seeders are 156 peers. In this situation CDN server can save energy, because with just 62.5% utilization and number additional 156 peers are served from seeders. We can see this situation as flat line in fig.6.6 from $N = 625$ until $N = 781$ In router case, we do not see router can get energy saving because number of traffic increase as increasing number of peers. For example, when CDN server on 50% utilization,

Figure 6.4: Dummy network

maximum number seeders are $n_s = 500$ and number of leechers can be served by seeders is 125 peers. Traffic traverse through router is 500Mbps plus additional 125Mbps. We get 125Mbps from 500 multiply to upload rate of seeders 0.25Mbps. Different air temperature supply, make different power consumption. With $T = 25$ or $COP = 3.194$, we can see the power consumption for all components decrease. That's because energy needed to supply air cooling with temperature $T = 25$ is less than energy needed to supply air cooling with temperature $T = 20$.

Next, Figure 6.7 shows energy consumption for CDN, router, and total energy consumption for CDN-P2P scenario. We use upload rate of seeders to leechers $\rho = 0.5$. We assume that CDN server utilization under 50%. For CDN server energy, the usage of energy increase until number of seeders $n_s = 500$. On $n_s = 500$ the CDN server right on 50% utilization. When CDN server on 50% utilization, maximum number of seeders are $n_s = 500$ and number of leechers can be served by seeders are 250 peers. In this situation, CDN server can save energy, because with just 50% utilization, additional 250 peers are served from seeders. We can see this situation as flat line in fig.6.6 from $N = 500$ until $N = 750$. In order to allow more peers, then CDN server must allow to increase its utilization from 50% to 75%. Again we will see flat line in fig.6.6 from $N = 750$ until $N = 1125$. That's because with CDN server utilization 75%, with number of seeders $n_s = 750$ can also serve leechers $n_l = 325$ leechers. On the other hand, energy consumption of router increasing with the increasing number of peers because router needs to accommodate traffic from all peers.

Figure 6.8 shows energy consumption for CDN, router, and total energy consumption for CDN-P2P scenario. We use upload rate of seeders to leechers $\rho = 0.75$. We assume that CDN server utilization under 50%. The result almost same with previous. CDN server energy increase until number of seeders $n_s = 500$. When CDN server hit 50% utilization, maximum number of seeders are $n_s = 500$ and number of leechers can be served by seeders are 325 peers. Therefore with same energy level on 50% utilization the system can server additional 325 peers. Again, for router energy consumption is increasing.

Figure 6.9 shows energy consumption for CDN, router, and total energy consumption for CDN-P2P scenario. We use upload rate of seeders to leechers $\rho = 1$. We assume that CDN server utilization under 50%. The result almost same with previous. CDN server energy increase until number of seeders $n_s = 500$. When CDN server hit 50% utilization, maximum number of seeders are $n_s = 500$ and number of leechers can be served by seeders are 500 peers. Therefore with same energy consumption level on 50% utilization the system can server additional 500 peers. Once again, router energy consumption is increasing.

Figure 6.5: CDN.

Figure 6.6: CDN-P2P $\rho = 0.25$.Figure 6.7: CDN-P2P $\rho = 0.5$.Figure 6.8: CDN-P2P $\rho = 0.75$.Figure 6.9: CDN-P2P $\rho = 1$.

Figure 6.10 shows percentage difference of energy consumption between CDN and CDN-P2P for CDN server component with $\rho = [0.25, 0.5, 0.75, 1]$. The power saving that CDN server get is from 3.8% to 11%. More clear figure is shown in fig.6.12 for $\rho = 0.75$ where CDN server can save energy because the utilization of CDN server is same when the system has number of peers from 500 to 875 and from 875 peers to 1531 are handle with same CDN utilization. Figure 6.11 shows percentage difference of energy consumption between CDN and CDN-P2P for total system with $\rho = [0.25, 0.5, 0.75, 1]$. The power saving that total system get is from 0.1% to 0.9%. Figure 6.13 reports percentage difference of energy consumption between CDN and CDN-P2P for total system with $\rho = 0.75$. While CDN server part can save more energy, due to peers high energy consumption then total energy saving in the system that we can get is small, from 0.2% to 0.9%.

6.3.2 Online Storage

In peer-assisted online storage, user contribute their upload bandwidth to redistribute of a file that they are downloading or that they have cached locally. We follow peer-assisted online storage model in [40] as basis of our work. In peer-assisted online storage, users can browse a catalog of available files and asynchronously issue request to download a given file, which are ideally immediately satisfied by the system. In order to reduce startup latency, first block of file must be downloaded from server [25]. In peer-assisted online storage, users interested to a specific file can retrieve it from servers (CDN) and from users storing copy of it in their computer or dedicated set top boxes/home gateway remotely. Peer-assisted online storage model in [40], the arrival process of request for considered file follow Poisson process, it takes into account multiple files of different popularity and server bandwidth provisioning. For detail, we refer the readers to [25, 40, 41]. All numerical simulation parameters that we used in this section same as [40].

6.4 Summary

In this paper, we have introduced the comparison of energy consumption between the peer-assisted CDN architecture and CDN architecture for live streaming and video on demand service. Integrating peer to peer capability to assist the existing CDN has a potential to save energy consumption. In this study, we show that

Figure 6.10: Different power consumption between CDN and CDN-P2P for CDN server component with $\rho = 0.25, 0.5, 0.75, 1$.

Figure 6.11: Different power consumption between CDN and CDN-P2P for total system with $\rho = 0.25, 0.5, 0.75, 1$.

Figure 6.12: Different power consumption between CDN and CDN-P2P for CDN server component with $\rho = 0.75$.

event without explicitly considering energy consumption while assigning content, the peer assisted CDN can save energy consumption. Our model shows that different peer-assisted CDN architecture for live streaming and online storage purpose can have different energy saving. Even different strategies in peer-assisted online storage can have different result.

Chapter 7

Conclusion and Future Work

7.1 Conclusion

We have investigated the properties of Bittorrent overlay topologies from the point of view of the peer exchange protocol using real swarms from an operational Bittorrent tracker on the Internet.

Our results agree in some particulars and disagree in others with prior published work on isolated testbed experiments, suggesting that more work is required to fully model the behavior of real-world Bittorrent networks.

We find that the node degree of the graph formed in a Bittorrent swarm can be described by a power law with exponential cut-off and the observation of a low clustering coefficient implies Bittorrent networks are close to random networks. From the Bittorrent protocol point of view, the reason that a Bittorrent swarm can be described by a power-law with exponential cut-off is: leechers in a Bittorrent swarm prefer a few good seeders or neighbors that can give high data rates to exchange the data and seeders have rich connections to leechers as seeders have complete chunks or pieces. That behavior explains why seeders have rich connections while leechers only have a few neighbors. We argue that there are two reasons for the cut-off phenomenon. First, most Bittorrent clients configure the maximum number of global connection between 200 – 300, however the maximum connection per torrent (swarm) is set between 50 – 90 by default [36] [46]. Some Bittorrent forums suggest decreasing the maximum connection for torrent (swarm) to between 30 – 40 [45]. Second, most of the Bittorrent users are home users where their home gateway device cannot give high concurrent connections and Bittorrent is not the main online activity. We argue that the Bittorrent swarm closes to random that we infer from clustering coefficient is caused by Bittorrent mechanism itself that always choose random peers from its neighbors in the choking-unchoking algorithm, optimistic choking algorithm, and optimistic connect algorithm as we explained previously.

Integrating peer to peer capability to assist the existing CDN has a potential to save energy consumption. In this study, we show that even without explicitly considering energy consumption while assigning content, the peer assisted CDN can save energy consumption. Although the energy savings depend on number of request (number of clients), number of router and its configuration, for total system energy saving is around 0.5 to 1.2. If we break per component, the CDN server is the part that can be pushed to save energy up to 11% and can be more if new generation of power proportional server is used [20]. We agree with [4], Router component in the other side is quite difficult for energy saving, because different chassis size, different network interface type slot, and different configuration has different energy consumption. Several areas that we have been identified for future work are: more correlation analysis of time period to peer energy usage pattern in live streaming, continued characterization of different peer energy usage based on flash memory storage, and comparing energy model with different file popularity models.

7.2 Future Work

Some areas of improvement that we have identified for future work are: more correlation analysis of the number of peers with α and p value, continued characterization with NATed peers, wider likelihood ratio test with other models and comparing the results with simulation for global graph properties such as distance distribution and spectrum. We hope to incorporate these properties into a complete dK series for the evolution of a real-world Bittorrent overlay as it evolves over time [26]. We conclude that further work throughout the community is necessary to continue to improve the agreement of simulation and controlled experiment with the real world, and that such work will impact our understanding of Bittorrent performance and its effects on the Internet. Several areas that we have been identified for future work in energy consumption of peer-assisted CDN: more correlation analysis of time period to peer energy usage pattern in live streaming, continued characterization of different peer energy usage based on flash memory storage, and comparing energy model with different file popularity models.
